432 Class 06

https://thomaselove.github.io/432-2023/

2023-02-02

Today's Agenda

- Data from the Heart and Estrogen/Progestin Study
- Using ols to fit linear regression models in the presence of missing values
- Using aregImpute to facilitate principled multiple imputation when fitting regressions
- Developing detailed regression results under a variety of imputation plans

Today's R Setup

```
knitr::opts chunk$set(comment = NA)
library(janitor)
library(broom)
library(knitr)
library(naniar)
library(simputation)
library(rms)
library(tidyverse)
theme_set(theme_bw())
```

Section 1

The HERS Data

Today's Data

Heart and Estrogen/Progestin Study (HERS)

- Clinical trial of hormone therapy for the prevention of recurrent heart attacks and deaths among 2763 post-menopausal women with existing coronary heart disease (see Hulley et al 1998 and many subsequent references, including Vittinghoff, Chapter 4.)
- We're excluding the women in the trial with a diabetes diagnosis.

The Codebook (n = 2032)

diabetes yes or no (all are no in our sample LDL cholesterol in mg/dl age age in years smoking yes or no drinkany yes or no sbp systolic BP in mm Hg physact 5-level factor, details next slide		1

Goal Predict 1dl using age, smoking, drinkany, sbp, physact and bmi, across both HT levels but restricted to women without diabetes.

The physact variable

hers1 |> count(physact)

```
# A tibble: 5 x 2
physact n
<chr> <int>
1 about as active 674
much less active 107
much more active 252
somewhat less active 322
somewhat more active 677
```

Comparison is to activity levels for these women just before menopause.

Any missing data?

miss_var_summary(hers1)

```
# A tibble: 10 \times 3
   variable n_miss pct_miss

```

Single Imputation for drinkany, bmi and 1dl

Since drinkany is a factor, we have to do some extra work to impute.

```
set.seed(432092)
hers2 <- hers1 |>
    mutate(drinkany n =
               ifelse(drinkany == "yes", 1, 0)) |>
    impute pmm(drinkany n ~ age + smoking) |>
    mutate(drinkany =
               ifelse(drinkany_n == 1, "yes", "no")) |>
    impute rlm(bmi ~ age + smoking + sbp) |>
    impute rlm(ldl ~ age + smoking + sbp + bmi)
```

Now, check missingness...

Multiple Imputation using aregImpute from Hmisc

Model to predict all missing values of any variables, using additive regression bootstrapping and predictive mean matching.

Steps are:

- aregImpute draws a sample with replacement from the observations where the target variable is observed, not missing.
- ② It then fits a flexible additive model to predict this target variable while finding the optimum transformation of it.
- It then uses this fitted flexible model to predict the target variable in all of the original observations.
- Finally, it imputes each missing value of the target variable with the observed value whose predicted transformed value is closest to the predicted transformed value of the missing value.

Fitting a Multiple Imputation Model

```

Iteration 9
```

Multiple Imputation using aregImpute from Hmisc

aregImpute requires specifications of all variables, and several other details:

- n.impute = number of imputations, we'll run 20
- nk = number of knots to describe level of complexity, with our choice
 nk = c(0, 3:5) we'll fit both linear models and models with
 restricted cubic splines with 3, 4, and 5 knots
- tlinear = FALSE allows the target variable to have a non-linear transformation when nk is 3 or more
- B = 10 specifies 10 bootstrap samples will be used
- data specifies the source of the variables

aregImpute Imputation Results (1 of 4)

fit3

Multiple Imputation using Bootstrap and PMM

```
aregImpute(formula = ~ldl + age + smoking + drinkany + sbp +
physact + bmi, data = hers1, n.impute = 20, nk = c(0, 3:5),
tlinear = FALSE, B = 10)
```

```
n: 2032 p: 7 Imputations: 20 nk: 0
```

A plot of the imputed values... (results)

A plot of the imputed values... (code)

```
par(mfrow = c(1,3)); plot(fit3); par(mfrow = c(1,1))
```

- For 1d1, we imputed most of the 7 missing subjects in most of the 20 imputation runs to values within a range of around 120 through 200, but occasionally, we imputed values that were substantially lower than 100.
- For drinkany we imputed about 70% no and 30% yes.
- For bmi, we imputed values ranging from about 23 to 27 in many cases, and up near 40 in other cases.
- This method never imputes a value for a variable that doesn't already exist in the data.

Analysis of Variance

Response: 1d1

Spearman ρ^2 Plot

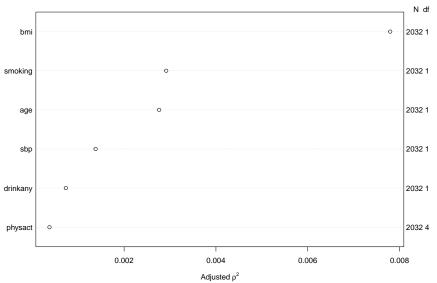

How should we prioritize the degrees of freedom we spend on non-linearity?

Plot's on the next page.

• Note the use of the simple imputation hers2 data here. Why?

Spearman ρ^2 Plot Result

Spending Degrees of Freedom

We're spending 9 degrees of freedom in our kitchen sink model. (We can verify this with anova or the plot.)

- Each quantitative main effect costs 1 df to estimate
- Each binary categorical variable also costs 1 df
- Multi-categorical variables with L levels cost L-1 df to estimate

Suppose we're willing to spend up to a total of ${\bf 14}$ degrees of freedom (i.e. a combined 5 more on interaction terms and other ways to capture non-linearity.)

What should we choose?

What did we see in the Spearman ρ^2 Plot?

Group 1 (largest adjusted ρ^2)

• bmi, a quantitative predictor, is furthest to the right

Group 2 (next largest)

- smoking, a binary predictor, is next, followed closely by
- age, a quantitative predictor

Other predictors (rest of the group)

- sbp, quantitative
- drinkany, binary
- physact, multi-categorical (5 levels)

Impact of Adding Non-Linear Terms on Spent DF

What happens when we add a non-linear term?

- Adding a polynomial of degree D costs D degrees of freedom.
 - So a polynomial of degree 2 (quadratic) costs 2 df, or 1 more than the main effect alone.
- Adding a restricted cubic spline with K knots costs K-1 df.
 - So adding a spline with 4 knots uses 3 df, or 2 more than the main effect.
 - We restrict ourselves to considering splines with 3, 4, or 5 knots.
- Adding an interaction (product term) depends on the main effects of the predictors we are interacting
 - If the product term's predictors have df1 and df2 degrees of freedom, product term adds df1 \times df2 degrees of freedom.
 - An interaction of a binary and quantitative variable adds $1 \times 1 = 1$ additional degree of freedom to the main effects model.
 - When we use a quantitative variable in a spline and interaction, we'll do the interaction on the main effect, not the spline.

Model we'll fit with ols

Fitting a model to predict 1d1 using

- bmi with a restricted cubic spline, 5 knots
- age with a quadratic polynomial
- sbp as a linear term
- drinkany indicator
- physact factor
- smoking indicator and its interaction with the main effect of bmi

We can fit this to the data

- restricted to complete cases (hers1, effectively)
- after simple imputation (hers2)
- after our multiple imputation (fit3)

Section 3

Using only the Complete Cases

Fitting the model to the complete cases

where %ia% identifies the linear interaction alone.

Making Predictions for an Individual

Suppose now that we want to use R to get a prediction for a new individual subject with bmi = 30, age = 50, smoking = yes and physact = about as active, drinkany= yes and <math>sbp of 150.

```
$linear.predictors $lower $upper
160.9399 88.48615 233.3936
```

Making Predictions for a Long-Run Mean

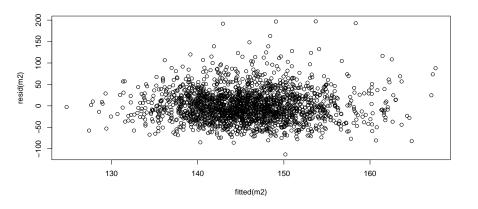

The other kind of prediction we might wish to make is for the mean of a series of subjects whose bmi = 30, age = 50, smoking = yes and physact = about as active, drinkany= yes and <math>sbp of 150.

```
$linear.predictors $lower $upper
160.9399 151.8119 170.0679
```

Of course, the confidence interval will always be narrower than the prediction interval given the same predictor values.

Residuals vs. Fitted Values?

```
plot(resid(m2) ~ fitted(m2))
```

Influential Points?

```
which.influence(m2, cutoff = 0.4)
$Intercept
[1] 1135
$age
[1] 1135
$smoking
[1] 132
$`smoking * bmi`
[1] 132
```

Section 5

Using Multiple Imputation

Fitting the Model using Multiple Imputation

What do we have now?

• An imputation model fit3

• A prediction model (from m1 or m2)

Now we put them together with the fit.mult.impute function...

Linear Regression & Imputation Model

- When you run this without the pr = FALSE it generates considerable output related to the imputations, which we won't use today.
- Let's look at the rest of the output this yields...

Adjusted to: bmi=26.9 smoking=no
```

plot(summary(m3imp))

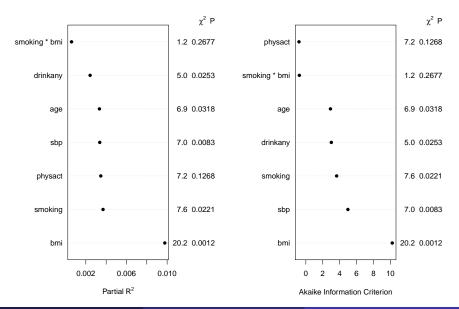

Adjusted to:bmi=26.9 smoking=no

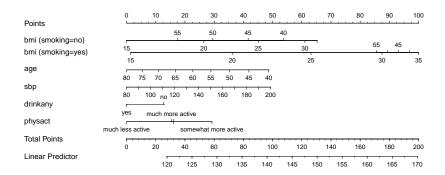

Evaluation via Partial \mathbb{R}^2 and AIC (code)

```
par(mfrow = c(1,2))
plot(anova(m3imp), what="partial R2")
plot(anova(m3imp), what="aic")
par(mfrow = c(1,1))
```

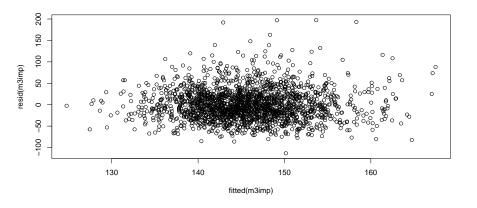

Evaluation via Partial R² and AIC (result)

plot(nomogram(m3imp))

plot(resid(m3imp) ~ fitted(m3imp))

Other Things I Might Need after aregImpute?

How can I estimate the AIC (and BIC) of a model fit with fit.mult.impute?

glance won't work with an ols fit, but we can just use...

AIC(m3imp)

d.f.

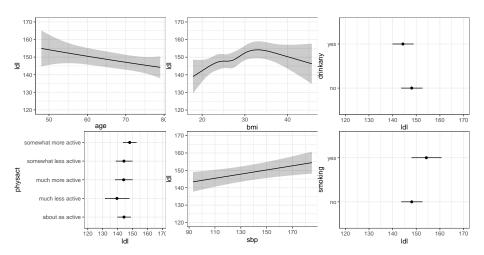

20425.29

BIC(m3imp)

d.f.

20515.16

Can I run ggplot(Predict(m3imp))?

Pull out one imputation from aregImpute?

How can I pull a single one (say, the fifth) of the imputations from aregImpute out?

Remember that fit3 was our imputation model here, build on the hers1 data, which keeps its subject identifiers in the subject column.

We'll show the result on the next slide.

Our fifth_imp tibble

Create Residual Plots for this imputation?

We can look at this model with glance or tidy to see that it gives similar results to what we see across the multiple imputations.

```
glance(model_for_resid_plots) |>
  select(r.squared, AIC, BIC, nobs, df, df.residual) |>
  kable(digits = 3)
```

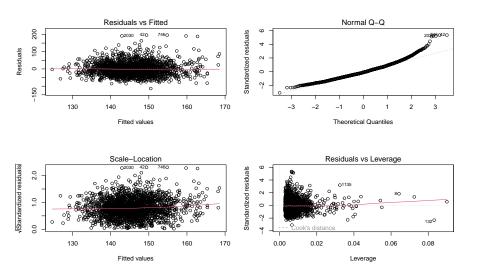

r.squared	AIC	BIC	nobs	df	df.residual
0.027	20451.36	20541.23	2032	14	2017

What else can we do?

We can plot residuals for the model fit to this single imputation, as shown on the next slide.

```
par(mfrow = c(2,2))
plot(model_for_resid_plots)
par(mfrow = c(1,1))
```
